Encoding UTF-8

Title Multivariate Normal Variance Mixtures

Description Functions for working with (grouped) multivariate normal variance mixture distributions (evaluation of distribution functions and densities, random number generation and parameter estimation), including Student's t distribution for non-integer degrees-of-freedom as well as the grouped t distribution and copula with multiple degrees-of-freedom parameters.

See <doi:10.18637/jss.v102.i02> for a high-level description of select functionality.

copula

Functionalities for Normal Variance Mixture Copulas

Description

Evaluate the density / distribution function of normal variance mixture copulas (including Student *t* and normal copula) and generate vectors of random variates from normal variance mixture copulas.

Usage

Arguments

u (n,d)-matrix of evaluation points or data; Have to be in (0,1). upper, lower (n,d)-matrix of upper/lower evaluation limits. Have to be in (0,1).

n sample size n (positive integer).

qmix specification of the mixing variable W; see pnvmix() for the ungrouped and

pgnvmix() for the grouped case.

groupings see pgnvmix().

df positive degress of freedom; can also be Inf in which case the copula is inter-

preted as the Gaussian copula.

scale scale matrix (a covariance matrix entering the distribution as a parameter) of di-

mension (d,d) (defaults to d=2); this equals the covariance matrix of a random vector following the specified normal variance mixture distribution divided by the expecation of the mixing variable W if and only if the former exists. Note that scale must be positive definite; sampling from singular ungrouped normal

variance mixtures can be achieved by providing factor.

factor (d,k)-matrix such that factor %*% t(factor) equals scale; the non-square

case $k \neq d$ can be used to sample from singular normal variance mixtures. For dnvmixcopula(), this has to be a square matrix. Note that this notation coincides with McNeil et al. (2015, Chapter 6). If not provided, factor is internally determined via chol() (and multiplied from the right to an (n, k)-matrix of independent standard normals to obtain a sample from a multivariate

normal with zero mean vector and covariance matrix scale).

factor.inv inverse of factor; if not provided, computed via solve(factor).

method see rnvmix().
skip see rnvmix().

df. init NULL or vector with initial estimates for df; can contain NAs.

df.bounds 2-vector with the lower/upper bounds on the degree-of-freedom parameter for

the fitting.

fit.method character indicating which fitting method is to be used; see details below.

x = (n, d)-matrix data matrix of which the underlying copula is to be estimated.

See also details below.

control list specifying algorithm specific parameters; see get_set_param().

verbose logical indicating whether a warning is given if the required precision abstol

has not been reached.

log logical indicating whether the logarithmic density is to be computed.

... additional arguments (for example, parameters) passed to the underlying mixing

distribution when rmix or qmix is a character string or function.

Details

Functionalities for normal variance mixture copulas provided here essentially call pnvmix(), dnvmix() and rnvmix() as well as qnvmix(), see their documentations for more details.

We remark that computing normal variance mixtures is a challenging task; evaluating normal variance mixture copulas additionally requires the approximation of a univariate quantile function so that for large dimensions and sample sizes, these procedures can be fairly slow. As there are approximations on many levels, reported error estimates for the copula versions of pnvmix() and dnvmix() can be flawed.

The functions [d/p/r]Studentcopula() are user-friendly wrappers for [d/p/r]nvmixcopula(, qmix = "inverse.gamma"), designed for the imporant case of a t copula with degrees-of-freedom df.

The function fitgStudentcopula() can be used to estimate the matrix scale and the degrees-of-freedom for grouped t-copulas. The matrix scale, if not provided, is estimated non-parametrically. Initial values for the degrees-of-freedom are estimated for each group separately (by fitting the corresponding marginal t copula). Using these initial values, the joint likelihood over all (length(unique(groupings))-many) degrees-of-freedom parameters is optimized via optim(). For small dimensions, the results are satisfactory but the optimization becomes extremely challenging when the dimension is large, so care should be taking when interpreting the results.

Value

The values returned by dnvmixcopula(), rnvmixcopula() and pnvmixcopula() are similar to the ones returned by their non-copula alternatives dnvmix(), rnvmix() and pnvmix().

The function fitgStudentcopula() returns an S3 object of class "fitgStudentcopula", basically a list which contains, among others, the components

df Estimated degrees-of-freedom for each group.

scale Estimated or provided scale matrix.

max.11 Estimated log-likelihood at reported estimates.

df.init Initial estimate for the degrees-of-freedom.

The methods print() and summary() are defined for the class "fitgStudentcopula".

dependencemeasures

Dependence Measures for grouped normal variance mixture copulas

Description

Computation of rank correlation coefficients Spearman's rho and Kendall's tau for grouped normal variance mixture copulas as well as computation of the (lower and upper) tail dependence coefficient of a grouped *t* copula.

Usage

Arguments

```
scale n-vector giving the \rho parameters of the copula.

qmix specification of the mixing variables; see pgnvmix().

method character indicating if Spearman's rho or Kendall's tau is to be computed.
```

dependencemeasures 7

groupings vector specifying the grouping structure; either rep(1, 2) (ungrouped) or 1:2 (grouped case).

ellip.kendall logical if the formula for Kendalll's tau for elliptical copulas shall be used; see

details below.

df either scalar or 2-vector giving the degrees-of- freedoms for the t copula; if pro-

vided as scalar, the copula is an (ungrouped) t copula and lambda_gStudent()

uses a closed formula.

control list specifying algorithm specific parameters; see get_set_param().

verbose logical indicating whether a warning is given if the required precision has not

been reached.

... additional arguments (for example, parameters) passed to the underlying mixing

distribution when qmix is a character string or function.

Details

For grouped normal variance mixture copulas, including the grouped *t*, there is no closed formula for Kendall's tau and Spearman's rho. The function corgnvmix() approximates these dependence measures by numerically approximating an integral representation for these measures.

If no grouping is present (i.e., when groupings = rep(1, 2)), the copula is an elliptical copula for which the formula $\tau = 2asin(\rho)/pi$ holds. This formula holds only approximately in the grouped case; the quality of the approximation depends on how different the mixing variables for the two components are. When the mixing distributions are not too far apart and when the copula parameter is not close to 1, this approximation is "very accurate", as demonstrated in Daul et al (2003).

In the ungrouped case, lambda_gStudent() computes the tail dependence coefficient lambda based on the known formula 2 * pt(-sqrt((df + 1)*(1 - rho) / (1 + rho)), df = df + 1) for the tail dependence coefficient of a t copula.

In the grouped case, RQMC methods are used to efficiently approximate the integral given in Eq. (26) of Luo and Shevchenko (2010).

Value

lambda_gStudent() and corgnvmix() return a numeric *n*-vector with the computed dependence measure with corresponding attributes "abs. error" and "rel. error"(error estimates of the RQMC estimator) and "numiter" (number of iterations).

Density of Grouped Normal Variance Mixtures

Description

Evaluating grouped normal variance mixture density functions (including Student *t* with multiple degrees-of-freedom).

Usage

Arguments

```
see dnvmix().
Χ
groupings
                  see pgnvmix().
                  specification of the mixing variables W_i via quantile functions; see pgnvmix().
qmix
loc
                  see pnvmix().
scale
                  see pnvmix(); must be positive definite.
factor
                  (d,d) lower triangular matrix such that factor %*% t(factor) equals scale.
                  Internally used is factor.inv.
factor.inv
                  inverse of factor; if not provided, computed via solve(factor).
df
                  vector of length length(unique(groupings)) so that variable i has degrees-
                  of-freedom df[groupings[i]]; all elements must be positive and can be Inf,
                  in which case the corresponding marginal is normally distributed.
control
                  list specifying algorithm specific parameters; see get_set_param().
                  logical indicating whether the logarithmic density is to be computed.
log
                  see pnvmix().
verbose
                  additional arguments (for example, parameters) passed to the underlying mix-
                  ing distribution when qmix is a character string or an element of qmix is a
                  function.
```

10 dgnvmix

Details

Internally used is factor.inv, so factor and scale are not required to be provided (but allowed for consistency with other functions in the package).

dgStudent() is a wrapper of dgnvmix(, qmix = "inverse.gamma", df = df). If there is no grouping, the analytical formula for the density of a multivariate t distribution is used.

Internally, an adaptive randomized Quasi-Monte Carlo (RQMC) approach is used to estimate the log-density. It is an iterative algorithm that evaluates the integrand at a randomized Sobol' point-set (default) in each iteration until the pre-specified error tolerance control\$dnvmix.reltol in the control argument is reached for the log-density. The attribute "numiter" gives the worst case number of such iterations needed (over all rows of x). Note that this function calls underlying C code.

Algorithm specific parameters (such as above mentioned control\$dnvmix.reltol) can be passed as a list via the control argument, see get_set_param() for details and defaults.

If the error tolerance cannot be achieved within control\$max.iter.rqmc iterations and fun.eval[2] function evaluations, an additional warning is thrown if verbose=TRUE.

Value

dgnvmix() and dgStudent() return a numeric n-vector with the computed density values and corresponding attributes "abs. error" and "rel. error" (error estimates of the RQMC estimator) and "numiter" (number of iterations).

12 dnymix

dnvmix

Density of Multivariate Normal Variance Mixtures

Description

Evaluating multivariate normal variance mixture densities (including Student *t* and normal densities).

Usage

Arguments

x	(n,d)-matrix of evaluation points.
qmix	specification of the mixing variable $W;$ see ${\tt pnvmix}()$ for details and examples.
df	positive degress of freedom; can also be Inf in which case the distribution is interpreted as the multivariate normal distribution with mean vector loc and covariance matrix scale).
loc	location vector of dimension d ; this equals the mean vector of a random vector following the specified normal variance mixture distribution if and only if the latter exists.
scale	scale matrix (a covariance matrix entering the distribution as a parameter) of dimension (d,d) ; this equals the covariance matrix of a random vector following the specified normal variance mixture distribution divided by the expectation of the mixing variable W if and only if the former exists. Needs to be full rank for the density to exist.
factor	(d,d) lower triangular matrix such that factor %*% t(factor) equals scale; note that for performance reasons, this property is not tested. If not provided, factor is internally determined via t(chol()).
control	<pre>list specifying algorithm specific parameters; see get_set_param().</pre>
log	logical indicating whether the logarithmic density is to be computed.

dnvmix 13

verbose logical indicating whether a warning is given if the required precision abstol

has not been reached.

. . . additional arguments (for example, parameters) passed to the underlying mixing

distribution when qmix is a character string or function.

Details

For the density to exist, scale must be full rank. Internally used is factor, so scale is not required to be provided if factor is given. The default factorization used to obtain factor is the Cholesky decomposition via chol().

dStudent() and dNorm() are wrappers of dnvmix(, qmix = "inverse.gamma", df = df) and dnvmix(, qmix = "constant"), respectively. In these cases, dnvmix() uses the analytical formulas for the density of a multivariate Student t and normal distribution, respectively.

Internally, an adaptive randomized Quasi-Monte Carlo (RQMC) approach is used to estimate the log-density. It is an iterative algorithm that evaluates the integrand at a randomized Sobol' point-set (default) in each iteration until the pre-specified error tolerance control\$dnvmix.reltol in the control argument is reached for the log-density. The attribute "numiter" gives the worst case number of such iterations needed (over all rows of x). Note that this function calls underlying C code.

Algorithm specific parameters (such as above mentioned control\$dnvmix.reltol) can be passed as a list via the control argument, see get_set_param() for details and defaults.

If the error tolerance cannot be achieved within control\$max.iter.rqmc iterations and fun.eval[2] function evaluations, an additional warning is thrown if verbose=TRUE.

Value

dnvmix(), dStudent() and dNorm() return a numeric *n*-vector with the computed (log-)density values and attributes "abs. error" and "rel. error" (containing the absolute and relative error estimates of the of the (log-)density) and "numiter" (containing the number of iterations).

fitnvmix

Fitting Multivariate Normal Variance Mixtures

Description

Functionalities for fitting multivariate normal variance mixtures (in particular also Multivariate *t* distributions) via an ECME algorithm.

Usage

Arguments

Х

(n,d)-data matrix.

qmix

specification of the mixing variable W; see McNeil et al. (2015, Chapter 6). Supported are the following types of specification (see also the examples below):

character: character string specifying a supported distribution; currently available are "constant" (in which case W=1 and thus the multivariate normal distribution with mean vector loc and covariance matrix scale results), "inverse.gamma" (in which case W is inverse gamma distributed with shape and rate parameters df/2 and thus the multivariate Student t distribution with df degrees of freedom results) and "pareto" (in which case t is Pareto distributed with scale equal to unity and shape equal to alpha).

function: function interpreted as the quantile function of the mixing variable W. In this case, qmix must have the form qmix = function(u, nu), where the argument nu corresponds to the parameter (vector) specifying the distribution of the mixing variable.

mix.param.bounds

either numeric(2) or a matrix with two columns. The first/second column corresponds to the lower/upper bound of nu_i , the ith component of the parameter vector nu of the mixing variable W. All elements need to be finite, numeric values. Note: The algorithm tends to converge quicker if the parameter ranges supplied are smaller.

nu.init

either NA or an initial guess for the parameter (vector) nu. In the former case an initial estimate is calculated by the algorithm. If nu.init is provided, the algorithm often converges faster; the better the starting value, the faster convergence.

16 fitnymix

loc d-vector; if provided, taken as the 'true' location vector in which case loc is

not estimated.

scale positive definite (d, d)-matrix; if provided, taken as the 'true' scale matrix in

which case scale is not estimated.

init.size.subsample

numeric, non-negative, giving the sub-samplesize used to get an initial estimate

for nu. Only used if is.na(nu.init), otherwise ignored.

size.subsample numeric, non-negative, specifying the size of the subsample that is being used

in the ECME iterations to optimize the log-likelihood over nu. Defaults to n, so that the full sample is being used. Decreasing this number can lead to faster run-times (as fewer log-densities need to be estimated) but also to an increase in

bias and variance.

control list specifying algorithm specific parameters; see below under 'Details' and

get_set_param().

verbose numeric or logical (in which case it is converted to numeric) specifying the

amount of tracing to be done. If \emptyset or FALSE, neither tracing nor warnigns are communicated; if 1, only warnigns are communicated, if 2 or 3, warnings and

(shorter or longer) tracing information is provided.

... additional arguments passed to the underlying fitnvmix().

Details

The function fitnvmix() uses an ECME algorithm to approximate the MLEs of the parameters nu, loc and scale of a normal variance mixture specified by qmix. The underlying procedure successively estimates nu (with given loc and scale) by maximizing the likelihood which is approximated by dnvmix() (unless qmix is a character string, in which case analytical formulas for the log-densities are used) and scale and loc (given nu) using weights (which again need to be approximated) related to the posterior distribution, details can be found in the first reference below.

It should be highlighted that (unless unless qmix is a character string), every log-likelihood and every weight needed in the estimation is numerically approximated via RQMC methods. For large dimensions and sample sizes this procedure can therefore be slow.

Various tolerances and convergence criteria can be changed by the user via the control argument. For more details, see get_set_param().

Value

The function fitnvmix() returns an S3 object of class "fitnvmix", basically a list which contains, among others, the components

nu Estimated mixing parameter (vector) nu.

loc Estimated or provided loc vector.

scale Estimated or provided scale matrix.

max.11 Estimated log-likelihood at reported estimates.

x Input data matrix x.

fitnvmix 17

The methods print(), summary() and plot() are defined for the class "fitnvmix".

fitStudent() is a wrapper to fitnvmix() for parameter estimation of multivariate Student *t* distributions; it also returns an S3 object of class "fitnvmix" where the fitted degrees of freedom are called "df" instead of "nu" (to be consistent with the other wrappers for the Student *t* distributions).

fitNorm() just returns a list with components loc (columnwise sample means) and scale (sample covariance matrix).

control
verbose
                  logical indicating whether a warning is given if the required precision has not
                  been reached.
                  additional arguments (for example, parameters) passed to the underlying mixing
                  distribution when qmix is a character string or function.
```

Details

We define a Gamma mixture as a random variable Dsq satisfying, in distribution, Dsq = W * Gamma(d/2,2) where W is specified via qmix. If X follows a d-dimensional normal variance mixture, the squared Mahalanobis distance $(X - \mu)^T Sigma^{-1}(X - \mu)$ has the same distribution as Dsq.

The functions presented here are similar to the corresponding functions for normal variance mixtures (d/p/q/rnvmix()), details can be found in the corresponding help-files there.

Value

pgammamix() and dgammamix() return a numeric *n*-vector with the computed probabilities/densities and corresponding attributes "abs. error" and "rel. error" (error estimates of the RQMC estimator) and "numiter" (number of iterations).

If q.only = TRUE, ggammamix() a vector of the same length as u with entries q_i where q_i satisfies $q_i = inf_x F(x) >= u_i$ where F(x) the df of the Gamma mixture specified via qmix; if q.only = FALSE, see qnvmix.

rgammamix() returns a *n*-vector containing *n* samples of the specified (via mix) Gamma mixture.

```

Description

Algorithm specific parameters for functionalities in the nvmix package, notably for fitnvmix(), dnvmix(), pnvmix(), qnvmix(), pgammamix(), dgammamix() and ES_nvmix() as well as the corresponding functions for grouped mixtures.

Usage

```
get_set_param(control = list())
```

Arguments

control

list specifying algorithm specific parameters to beset; see below under details.

Details

For most functions in the nvmix package, internally, an iterative randomized Quasi-Monte Carlo (RQMC) approach is used to estimate probabilities, weights and (log-)densities. There are various parameters of underlying methods than can be changed.

Algorithm specific parameters can be passed as a list via control. It can contain any of the following:

For all algorithms: method character string indicating the method to be used to compute the integral. Available are:

"sobol": Sobol' sequence (default),

"ghalton": generalized Halton sequence,

"PRNG": plain Monte Carlo based on a pseudo-random number generator.

increment character string indicating how the sample size should be increased in each iteration. Available are:

"doubling": next iteration has as many sample points as all the previous iterations combined.

"num.init": all iterations use an additional fun.eval[1]-many points (default for most functions).

- CI. factor multiplier of the Monte Carlo confidence interval bounds. The algorithm runs until CI. factor times the estimated standard error is less than abstol or reltol (whichever is provided). If CI. factor = 3.5 (the default), one can expect the actual absolute error to be less than abstol in 99.9% of the cases.
- fun.eval numeric(2) providing the size of the first point set to be used to estimate integrals (typically a power of 2) and the maximal number of function evaluations. fun.eval defaults to c(2^7, 1e12).
- max.iter.rqmc numeric, providing the maximum number of iterations allowed in the RQMC approach; the default is 15 if increment = "doubling" and 1250 otherwise.
- B number of randomizations for obtaining an error estimate in the RQMC approach; the default is 15.
- For pnvmix() and pgnvmix(): pnvmix.abstol, pnvmix.reltol non-negative numeric providing the relative/absolute precision required for the distribution function. Relative precision via pnvmix.reltol is only used when pnvmix.abstol = NA; in all other cases, absolute precision will be used. pnvmix.abstol defaults to 1e-3. If pnvmix.abstol

= 0 and pnvmix.reltol = 0, the algorithm will typically run until the total number of function evaluations exceeds fun.eval[2] or until the total number of iterations exceeds max.iter.rqmc, whichever happens first. If n > 1 (so upper has more than one row), the algorithm runs until the precision requirement is reached for all n probability estimates.

- mean.sqrt.mix expectation of the square root $\sqrt(W)$ of the mixing variable W. If NULL, it will be estimated via QMC; this is only needed for determining the reordering of the integration bounds, so a rather crude approximation is fine.
- precond logical indicating whether preconditioning is applied, that is, reordering of the integration variables. If TRUE, integration limits lower, upper as well as scale are internally re-ordered in a way such that the overall variance of the integrand is usually smaller than with the original ordering; this usually leads smaller run-times.
- cholesky.tol non-negative numeric providing lower threshold for non-zero elements in the computation of the cholesky factor: If calculated $C(i,i)^2 < |cholesky.tol*Scale(i,i)|$, the diagonal element (and all other elements in column i) of the cholesky factor C are set to zero, yielding a singular matrix. cholesky.tol defaults to 1e-9.
- For dnvmix() and dgnvmix(): dnvmix.reltol, dnvmix.abstol non-negative numeric providing the relative/absolute precision for the *log-* density required. Absolute precision via dnvmix.abstol is only used when dnvmix.reltol = NA; in all other cases, relative precision will be used. dnvmix.reltol defaults to 1e-2. If dnvmix.reltol=0 and dnvmix.abstol=0, the algorithm will typically run until the total number of function evaluations exceeds fun.eval[2] or until the total number of iterations exceeds max.iter.rqmc, whichever happens first. If n > 1 (so x has more than one row), the algorithm runs until the precision requirement is reached for all n log-density estimates.
 - dnvmix.doAdapt logical indicating if an adaptive integration procedure shall be used that only samples in relevant subdomains of the mixing variable; defaults to TRUE.
 - dnvmix.max.iter.rqmc.pilot numeric, providing the maximum number of unstratified, non-adaptive pilot runs the internal integration procedure performs. Defaults to 6.
 - dnvmix.tol.int.lower, dnvmix.order.lower both numeric and nonnegative. RQMC integration is only performed where the integrand is > than the maximum of dnvmix.tol.int.lower and $10^{-c}g_{max}$, where g_{max} is the theoretical maximum of the integrand and c is the specified dnvmix.order.lower. Default to 1e-100 and 5, respectively.
 - dnvmix.tol.bisec numeric vector of length 3 specifying bisection tolerances in the adaptive RQMC algorithm. First/second/third element specify the tolerance on u, W and the log-integrand and default to 1e-6, 1e-1 and 1e-1, respectively.
 - dnvmix.max.iter.bisec numeric, maximum number of iterations in the internal bisection procedure to find good cutting points allowed, defaults to 15.
 - dnvmix.tol.stratlength numeric, nonnegative. If the stratum found by the adaptive integration method has length > dnvmix.tol.stratlength RQMC integration is used there; otherwise a crude approximation. Defaults to 1e-50.
- **For** fitnvmix(): ECMEstep logical, if TRUE (default), ECME iteration is performed; if FALSE, no ECME step is performed so that fitnvmix() performs between zero and two optimizations over nu, depending on laststep.do.nu and whether nu.init was provided.
 - ECMEstep.do.nu logical, if TRUE (default), the likelihood is maximized over nu in each ECME iteration; if FALSE, this step is omitted.
 - laststep.do.nu logical, if TRUE another last maximization of the likelihood over nu is performed using all observations after the ECME iterations. Only makes sense if either

- ECMEstep.do.nu=FALSE or if size.subsample is smaller than the number of observations. Defaults to FALSE.
- resample logical, if TRUE, a different subsample of x is taken in each optimization over nu in the ECME iterations. Only relevant when size. subsample is smaller than the number of observations. Defaults to FALSE.
- ECME.miniter, ECME.maxiter numeric positive, minimum and maximum number of ECME iterations. Default to 5 and 200, respectively.
- max.iter.locscaleupdate numeric positive. Maximum number of location-scale updates (while helding nu fixed) in each individual ECME iteration; defaults to 50.
- weights.reltol numeric non-negative. Relative tolerance to estimate internal weights used to update *loc* and *scale* estimates in the ECME iterations. Defaults to 1e-2.
- weights.interpol.reltol numeric non-negative. Some weights can be obtained by interpolating previously calculated weights; if the maximal relative interpolation error is smaller than weights.interpol.reltol, this is done. Defaults to 1e-2.
- ECME.rel.conv.tol numeric(3) vector specifying relative convergence tolerances for loc, scale and nu (in this order). Defaults to c(1e-2, 1e-2, 1e-3).
- control.optim list of control parameters passed to the underlying optim in the initial step as well as in the ECME iterations. See optim() for details; defaults to list(maxit=75).
- control.optim.laststep like control.optim; this list of control arguments is passed to
 optim in the last-step. Only relevant when laststep.do.nu = TRUE and defaults to
 list() (so no defaults of optim() changed).
- **For** qnvmix(): max.iter.newton numeric, maximum number of Newton iterations allowed to approximate the quantile; defaults to 45.
 - newton.conv.abstol numeric, convergence tolerance for the Newton proceudre; convergence is detected once the difference of estimated quantiles in two successive iterations is smaller than newton.conv.abstol; defaults to 5e-4.
 - newton.df.reltol numeric, relative error tolerance for estimating the univariate distribution function; defaults to 2.5e-4.
 - newton.logdens.abstol numeric, absolute error tolerance for the internal estimation of the log-density needed for the update; defaults to 1e-2.
 - newton.df.max.iter.rqmc numeric, maximum number of iterations to estimate the univariate distribution function required in the Newton update; defaults to 350. Note that internally used is increment = "doubling", no matter what.
- **For** qqplot_maha(): qqplot.df.reltol numeric, with the same meaning as newton.df.reltol for the function qnvmix(). Defaults to 5e-3.

Care should be taken when changing algorithm specific parameters, notably tolerances, as the accuracy of the result is heavily influenced by those.

Value

get_set_param() returns a list with more than 30 elements specifying algorithm specific parameters for the functions fitnvmix(), dnvmix(), pnvmix(), qnvmix(), pgammamix(), dgammamix()

24 get_set_qqplot_param

and ES_nvmix(), as well as the corresponding functions for grouped mixtures such as pgnvmix() and dgnvmix(). Parameter values passed to get_set_param() via the control argument overwrite the defaults; for parameters not specified in the control argument, the default values are being returned.

Examples

```
get_set_param() # obtain defaults
```

```
get_set_qqplot_param
Plotting parameters for QQ Plots
```

Description

Plotting parameters for the method plot() of the class qqplot_maha.

Usage

```
get_set_qqplot_param(plot.pars = list(log = ""))
```

Arguments

plot.pars list specifying plotting parameters to be set; see below under details.

Details

This function provides a convenient way to set plotting parameters in the argument plot.pars of the function qqplot_maha() (more precisely, the underlying plot() method), such as logarithmic plotting, colors, linetypes and more.

The input list plot.pars can contain any of the following:

```
log character specifying the logarithmic axes. Just like for the generic plot, must be one of "", "x", "y" or "xy".
```

xlim, ylim The x- and y-limits for plotting.

xlab, ylab character specifying the x- and y-axis labels. Default to "Theoretical quantiles" and "Sample quantiles", respectively.

sub, main character specifying title and subtitle of the plot; default to "", so no titles.

plot_legend, plot_test, plot_line logical specifying if a legend should be plotted; if the test result of the GoF test should be displayed on the 3rd axis and if the plot should contain a fitted line. All default to TRUE.

pch specification of the plotting symbol; see ?points(). Defaults to 1.

- 1ty 3-vector containing the specification of the linetypes for i) the diagonal, ii) the asymptotic CI and iii) the bootstrap CI; see also ?par(). Defaults to 1:3.
- col 4-vector specifying the colors to be used for i) the points in the QQ plot; ii) the diagonal; iii) the asymptotic CI and iv) the bootstrap CI. Defaults to c("black", "red", "azure4", "chocolate4").

Value

get_set_qqplot_param() returns a list with 13 elements that is passed to qqplot_maha(), more specifically, to the underlying plot() method. Parameter values passed to get_set_qqplot_param() via the plot.pars argument overwrite the defaults; for parameters not specified in the plot.pars argument, the default values are being returned.

Data Generated by the Demo 'numerical_experiments'

Description

Data generated by the demo('numerical_experiments') of the nvmix package.

Usage

```
data(numerical_experiments_data, package = "nvmix")
```

Format

A list with 10 elements:

- \$pnvmix.abserrors Array as returned by the function pnvmix_testing_abserr(), see Section
 1.1 of the demo('numerical_experiments').
- \$pnvmix.t.variances Array as returned by the function precond_testing_variance(), see Section 1.1 of the demo('numerical_experiments').
- \$pnvmix.t.sobolind Array as returned by the function pnvmix_estimate_sobolind(), see Section 1.1 of the demo('numerical_experiments').
- \$pnvmix.t.timing Array as returned by the function pnvmix_timing_mvt(), see Section 1.1 of
 the demo('numerical_experiments').
- \$dnvmix.results Array as returned by the function dnvmix_testing(), see Section 1.2 of the demo('numerical_experiments').
- \$fitnvmix.results Array as returned by the function fitnvmix_testing(), see Section 1.3 of
 the demo('numerical_experiments').
- \$fit.dj30.anaylytical Array containing results of fitnvmix() applied to DJ30 data using analytical weights/densities, see Section 5 of demo('numerical_experiments').
- \$fit.dj30.estimated Array containing results of fitnvmix() applied to DJ30 data using estimated weights/densities, see Section 5 of demo('numerical_experiments').
- \$qqplots.dj30 Array containing results of qqplot.maha() applied to DJ30 data, see Section 5 of the demo('numerical_experiments').
- \$tailprobs.dj30 Array containing estimated quantile shortfall probabilities of models fitted to DJ30 data, see Section 5 of demo('numerical_experiments').

pgnvmix	Distribution Function of Grouped Multivariate Normal Variance Mixtures
	tures

Description

Evaluating grouped and generalized multivariate normal variance mixture distribution functions (including Student *t* with multiple degrees-of-freedom).

Usage

```
pgnvmix(upper, lower = matrix(-Inf, nrow = n, ncol = d), groupings = 1:d, qmix,
        rmix, loc = rep(0, d), scale = diag(d), standardized = FALSE,
       control = list(), verbose = TRUE, ...)
pgStudent(upper, lower = matrix(-Inf, nrow = n, ncol = d), groupings = 1:d, df,
          loc = rep(0, d), scale = diag(d), standardized = FALSE,
          control = list(), verbose = TRUE)
```

Arguments

qmix

upper see pnvmix(). lower see pnvmix().

d-vector. Specification of the groupings so that variable i has mixing variable groupings

 W_k where k = groupings[i]. If groupings = 1:d, each variable has a different

mixing distribution.

specification of the mixing variables W_i via quantile functions; see McNeil et al. (2015, Chapter 6) and Hintz et al. (2020). Supported are the following types of specification (see also the examples below):

> character: character string specifying a supported distribution; currently available are "inverse gamma" (in which case W_i is inverse gamma distributed with shape and rate parameters df[groupings[i]]/2 and a multivariate Student t distribution multiple degreess-of-freedom results) and "pareto" (in which case W_i is Pareto distributed with scale equal to unity and shape equal to alpha[groupings[i]]. alpha and df must be of length length(unique(groupings)) and need to be provided via the ellipsis argument).

> list: list of length length(unique(groupings)) (number of different mixing distributions). Element i of this list specifies the mixing variable for component groupings[i]. Each element of this list can be

list: a list of length at least one, where the first component is a character string specifying the base name of a distribution whose quantile function can be accessed via the prefix "q". An example "exp" for which "qexp" exists. If the list is of length larger than one, the remaining elements contain additional parameters of the distribution; for "exp", for example, this can be the parameter rate.

function: function interpreted as the quantile function or random number generator of the mixing variable W_i

only allowed when groupings = rep(1, d) in which case pgnvmix() is equiv-

alent to pnvmix(); see pnvmix().

vector of length length(unique(groupings)) so that variable i has degreesof-freedom df[groupings[i]]; all elements must be positive and can be Inf,

in which case the corresponding marginal is normally distributed.

loc see pnvmix().

see pnvmix(); must be positive definite. scale

rmix

df

standardized see pnvmix().

control list specifying algorithm specific parameters; see get_set_param().

verbose see pnvmix().

.. additional arguments (for example, parameters) passed to the underlying mix-

ing distribution when qmix is a character string or an element of qmix is a

function.

Details

One should highlight that evaluating grouped normal variance mixtures is a non-trivial tasks which, at the time of development of **nvmix**, was not available in R before, not even the special case of a multivariate Student *t* distribution for non-integer degrees of freedoms, which frequently appears in applications in finance, insurance and risk management after estimating such distributions.

Internally, an iterative randomized Quasi-Monte Carlo (RQMC) approach is used to estimate the probabilities. It is an iterative algorithm that evaluates the integrand at a point-set (with size as specified by control\$increment in the control argument) in each iteration until the pre-specified absolute error tolerance control\$pnvmix.abstol (or relative error tolerance control\$pnvmix.reltol which is used only when control\$pnvmix.abstol = NA) is reached. The attribute "numiter" gives the number of such iterations needed. Algorithm specific parameters (such as the above mentioned control\$pnvmix.abstol) can be passed as a list via control, see get_set_param() for more details. If specified error tolerances are not reached and verbose = TRUE, a warning is thrown.

pgStudent() is a wrapper of pgnvmix(, qmix = "inverse.gamma", df = df).

Value

pgnvmix() and pgStudent() return a numeric *n*-vector with the computed probabilities and corresponding attributes "abs. error" and "rel. error" (error estimates of the RQMC estimator) and "numiter" (number of iterations).

pnvmix

Distribution Function of Multivariate Normal Variance Mixtures

Description

Evaluating multivariate normal variance mixture distribution functions (including Student t and normal distributions).

Usage

Arguments

upper

(n,d)-matrix of upper integration limits; each row represents a d-vector of upper integration limits.

lower

(n,d)-matrix of lower integration limits (componentwise less than or equal to upper); each row represents a d-vector of lower integration limits.

qmix, rmix

specification of the mixing variable W via a quantile function (qmix) (recommended, see details below) *or* random number generator (rmix); see McNeil et al. (2015, Chapter 6) and Hintz et al. (2020). Supported are the following types of specification (see also the examples below):

character: character string specifying a supported distribution; currently available are "constant" (in which case W=1 and thus the multivariate normal distribution with mean vector loc and covariance matrix scale results), "inverse.gamma" (in which case W is inverse gamma distributed with shape and rate parameters df/2 and thus the multivariate Student t distribution with df degrees of freedom (required to be provided via the ellipsis argument) results) and "pareto" (in which case W is Pareto distributed with scale equal to unity and shape equal to alpha, which needs to be provided via the ellipsis argument).

list: list of length at least one, where the first component is a character string specifying the base name of a distribution whose quantile function or random number generator can be accessed via the prefix "q" and "r", respectively. an example is "exp" for which "qexp" exists. If the list is of length larger than one, the remaining elements contain additional parameters of the distribution; for "exp", for example, this can be the parameter rate.

function: function interpreted as the quantile function or random number generator of the mixing variable W.

df positive degress of freedom; can also be Inf in which case the distribution is

interpreted as the multivariate normal distribution with mean vector loc and

covariance matrix scale.

loc location vector of dimension d; this equals the mean vector of a random vector

following the specified normal variance mixture distribution if and only if the

latter exists.

scale scale matrix (a covariance matrix entering the distribution as a parameter) of

dimension (d,d); this equals the covariance matrix of a random vector following the specified normal variance mixture distribution divided by the expectation of the mixing variable W if and only if the former exists. scale is allowed to be singular in which case the distribution function of the singular normal variance

mixture is returned.

standardized logical indicating whether scale is assumed to be a correlation matrix.

control list specifying algorithm specific parameters; see get_set_param().

verbose logical indicating whether a warning is thrown if the required precision pnvmix.abstol

or pnvmix.reltol as specified in the control argument has not been reached; can also be an integer in which case 0 is FALSE, 1 is TRUE and 2 stands for producing a more verbose warning (for each set of provided integration bounds).

.. additional arguments (for example, parameters) passed to the underlying mixing

distribution when qmix is a character string or function.

Details

One should highlight that evaluating normal variance mixtures is a non-trivial tasks which, at the time of development of **nvmix**, was not available in R before, not even the special case of a multivariate Student t distribution for non-integer degrees of freedom, which frequently appears in applications in finance, insurance and risk management after estimating such distributions.

Note that the procedures call underlying C code. Currently, dimensions $d \geq 16510$ are not supported for the default method sobol.

Internally, an iterative randomized Quasi-Monte Carlo (RQMC) approach is used to estimate the probabilities. It is an iterative algorithm that evaluates the integrand at a point-set (with size as specified by control\$increment in the control argument) in each iteration until the pre-specified absolute error tolerance control\$pnvmix.abstol (or relative error tolerance control\$pnvmix.reltol which is used only when control\$pnvmix.abstol = NA) is reached. The attribute "numiter" gives the number of such iterations needed. Algorithm specific parameters (such as the above mentioned control\$pnvmix.abstol) can be passed as a list via control, see get_set_param() for more details. If specified error tolerances are not reached and verbose = TRUE, a warning is thrown.

If provided scale is singular, pnvmix() estimates the correct probability but throws a warning if verbose = TRUE.

It is recommended to supply a quantile function via qmix, if available, as in this case efficient RQMC methods are used to approximate the probability. If rmix is provided, internally used is plain MC integration, typically leading to slower convergence. If both qmix and rmix are provided, the latter is ignored.

pStudent() and pNorm() are wrappers of pnvmix(, qmix = "inverse.gamma", df = df) and pnvmix(, qmix = "constant"), respectively. In the univariate case, the functions pt() and pnorm() are used.

Value

pnvmix(), pStudent() and pNorm() return a numeric *n*-vector with the computed probabilities and corresponding attributes "abs. error" and rel. error (error estimates of the RQMC estimator) and "numiter" (number of iterations).

```

qnvmix

Quantile Function of a univariate Normal Variance Mixture Distribution

Description

Evaluating multivariate normal variance mixture distribution functions (including normal and Student *t* for non-integer degrees of freedom).

Usage

```
qnvmix(u, qmix, control = list(),
     verbose = TRUE, q.only = TRUE, stored.values = NULL, ...)
```

qnvmix 35

Arguments

u	vector of probabilities .
qmix	specification of the mixing variable $W;$ see $\operatorname{pnvmix}()$ for details and examples.
control	<pre>list specifying algorithm specific parameters; see get_set_param().</pre>
verbose	logical, if TRUE a warning is printed if one of the error tolerances is not met.
q.only	${\tt logical}.$ If TRUE, only the quantiles are returned; if FALSE, see Section 'value' below.
stored.values	<code>matrix</code> with 3 columns of the form $[x,F(x),logf(x)]$ where $F()$ and $logf()$ are the distribution- and log-density function of the distribution specified in qmix. If provided it is used to determine starting values for internal newton procedures. Only very basic checking is done.
	additional arguments containing parameters of mixing distributions when \ensuremath{qmix} is a character string.

Details

This function uses a Newton procedure to estimate the quantile of the specified univariate normal variance mixture distribution. Internally, a randomized quasi-Monte Carlo (RQMC) approach is used to estimate the distribution and (log)density function; the method is similar to the one in pnvmix() and dnvmix(). The result depends slightly on .random.seed.

Internally, symmetry is used for $u \leq 0.5$. Function values (i.e., df and log-density values) are stored and reused to get good starting values. These values are returned if q.only = FALSE and can be re-used by passing it to qnvmix() via the argument stored.values; this can significantly reduce run-time.

Accuracy and run-time depend on both the magnitude of u and on how heavy the tail of the underlying distributions is. Numerical instabilities can occur for values of u close to 0 or 1, especially when the tail of the distribution is heavy.

If q.only = FALSE the log-density values of the underlying distribution evaluated at the estimated quantiles are returned as well: This can be useful for copula density evaluations where both quantities are needed.

Underlying algorithm specific parameters can be changed via the control argument, see get_set_param() for details.

Value

```
If q. only = TRUE a vector of the same length as u with entries q_i where q_i satisfies q_i = inf_x F(x) \ge u_i where F(x) the univariate df of the normal variance mixture specified via qmix; if q. only = FALSE a list of four: $q: Vector of quantiles, $log.density: vector log-density values at q, $computed.values: matrix with 3 columns [x, F(x), logf(x)]; see details above, $newton.iterations: vector giving the number of Newton iterations needed for u[i].
```

qqplot_maha

QQ Plot for Multivariate Normal Variance Mixtures

Description

Visual goodness-of-fit test for multivariate normal variance mixtures: Plotting squared Mahalanobis distances against their theoretical quantiles.

qqplot_maha 37

Usage

Arguments

(n,d)-data matrix. Х see pnvmix(). qmix loc see pnvmix(). scale see pnvmix(). fitnvmix_object Optional. Object of class "fitnvmix" typically returned by fitnvmix(); if provided, x, qmix, loc and scale are ignored. trafo.to.normal logical. If TRUE, the underlying Mahalanobis distances are mapped to normals by a probability- quantile-transform so that the resulting QQ plot is essentially a normal QQ plot. Defaults to FALSE. character specifying if (and which) GoF test shall be performed. "KS" pertest forms a Kolmogorov-Smirnoff (see ks.test()), "AD" an Anderson-Darling test (see ad.test() from the package ADGofTest and "none" performs no test. By default, test = "KS.AD" in which case both tests are performed. boot.pars list with elements B (Bootstrap sample size for computing CIs; if B <= 1, no Bootstrap is performed) and level specifying the confidence level. plot logical specifying if the results should be plotted. verbose see pnvmix(). control see get_set_param(). integer specifying the number of digits of the test statistic and the p-value to be digits displayed. plot.pars list specifying plotting parameters such as logarithmic axes; see get_set_qqplot_param(). additional arguments (for example, parameters) passed to the underlying mixing

Details

If X follows a multivariate normal variance mixture, the distribution of the Mahalanobis distance $D^2 = (X - \mu)^T \Sigma^{-1} (X - \mu)$ is a gamma mixture whose distribution function can be approximated.

distribution when qmix is a character string or function.

The function qqplot_maha() first estimates the theoretical quantiles by calling qgammamix() and then plots those against the empirical squared Mahalanobis distances from the data in x (with μ =loc and Σ =scale). Furthermore, the function computes asymptotic standard errors of the sample quantiles by using an asymptotic normality result for the order statistics which are used to plot the asymptotic CI; see Fox (2008, p. 35 – 36).+

38 qqplot_maha

If boot.pars\$B > 1 (which is the default), the function additionally performs Bootstrap to construct a CI. Note that by default, the plot contains both the asymptotic and the Bootstrap CI.

Finally, depending on the parameter test, the function performs a univariate GoF test of the observed Mahalanobis distances as described above. The test result (i.e., the value of the statistic along with a p-value) are typically plotted on the second y-axis.

The return object of class "qqplot_maha" contains all computed values (such as p-value, test-statistics, Bootstrap CIs and more). We highlight that storing this return object makes the QQ plot quickly reproducible, as in this case, the theoretical quantiles do not need to be recomputed.

For changing plotting parameters (such as logarithmic axes or colors) via the argument plot.pars, see get_set_qqplot_param().

Value

qqplot_maha() (invisibly) returns an object of the class "qqplot_maha" for which the methods plot() and print() are defined. The return object contains, among others, the components

maha2 Sorted, squared Mahalanobis distances of the data from loc wrt to scale.

theo_quant The theoretical quantile function evaluated at ppoints(length(maha2)).

boot_CI (2, length(maha2)) matrix containing the Bootstrap CIs for the empirical quantiles.

asymptSE vector of length length(maha2) with estimated, asympotic standard errors for the empirical quantiles.

riskmeasures

Risk measures for normal variance mixtures

Description

Estimation of value-at-risk and expected shortfall for univariate normal variance mixtures

riskmeasures 43

Usage

```
VaR_nvmix(level, qmix, loc = 0, scale = 1, control = list(), verbose = TRUE, ...)
ES_nvmix(level, qmix, loc = 0, scale = 1, control = list(), verbose = TRUE, ...)
```

Arguments

level	n-vector of confidence levels.
qmix	see pnvmix().
loc	numeric location, see also pnvmix()
scale	<pre>numeric scale, see also pnvmix()</pre>
control	list specifying algorithm specific parameters; see <pre>get_set_param()</pre> .
verbose	logical indicating whether a warning is given if the required precision has not been reached.
•••	additional arguments (for example, parameters) passed to the underlying mixing distribution when qmix is a character string or function, see also pnvmix()

Details

VaR_nvmix calls qnvmix().

The function ES_nvmix() estimates the expected shortfall using a randomized quasi Monte Carlo procedure by sampling from the mixing variable specified via qmix and and using the identity $\int_k^\infty x\phi(x)dx=\phi(k)$ where $\phi(x)$ denotes the density of a standard normal distribution. Algorithm specific paramaters (such as tolerances) can be conveniently passed via the control argument, see get_set_param() for more details.

Value

VaR_nvmix() and ES_nvmix() return a numeric *n*-vector with the computed risk measures and in case of ES_nvmix() corresponding attributes "abs. error" and "rel. error"(error estimates of the RQMC estimator) and "numiter" (number of iterations).

rnvmix

(Quasi-)Random Number Generation for Multivariate Normal Variance Mixtures

Description

Generate vectors of random variates from multivariate normal variance mixtures (including Student *t* and normal distributions).

Usage

Arguments

n

sample size n (positive integer).

rmix

specification of the mixing variable W, see McNeil et al. (2015, Chapter 6) and Hintz et al. (2020), via a random number generator. This argument is ignored for method = "sobol" and method = "ghalton". Supported are the following types of specification (see also the examples below):

character: character string specifying a supported distribution; currently available are "constant" (in which case W=1 and thus a sample from the multivariate normal distribution with mean vector loc and covariance matrix scale results) and "inverse.gamma" (in which case W is inverse gamma distributed with shape and rate parameters df/2 and thus the multivariate Student t distribution with df degrees of freedom (required to be provided via the ellipsis argument) results).

list: list of length at least one, where the first component is a character string specifying the base name of a distribution which can be sampled via prefix "r"; an example is "exp" for which "rexp" exists for sampling. If the list is of length larger than one, the remaining elements contain additional parameters of the distribution; for "exp", for example, this can be the parameter rate.

function: function interpreted as a random number generator of the mixing variable W; additional arguments (such as parameters) can be passed via the ellipsis argument.

numeric: numeric vector of length n providing a random sample of the mixing variable W.

specification of the mixing variable W via a quantile function. This argument is required for method = "sobol" and method = "ghalton". Supported are the following types of specification (see also the examples below):

character: character string specifying a supported distribution; currently available are "constant" (in which case W=1 and thus a sample from the multivariate normal distribution with mean vector loc and covariance matrix scale results) and "inverse.gamma" (in which case W is inverse gamma distributed with shape and rate parameters df/2 and thus the multivariate Student t distribution with df degrees of freedom (required to be provided via the ellipsis argument) results).

list: list of length at least one, where the first component is a character string specifying the base name of a distribution which can be sampled via prefix "q"; an example is "exp" for which "qexp" exists for sampling. If the list is of length larger than one, the remaining elements contain additional parameters of the distribution; for "exp", for example, this can be the parameter rate.

function: function interpreted as the quantile function of the mixing variable W; internally, sampling is then done with the inversion method by applying the provided function to U(0,1) random variates.

positive degress of freedom; can also be Inf in which case the distribution is interpreted as the multivariate normal distribution with mean vector loc and covariance matrix scale).

location vector of dimension d; this equals the mean vector of a random vector following the specified normal variance mixture distribution if and only if the latter exists.

scale matrix (a covariance matrix entering the distribution as a parameter) of dimension (d,d) (defaults to d=2); this equals the covariance matrix of a random vector following the specified normal variance mixture distribution divided by the expecation of the mixing variable W if and only if the former exists. Note that scale must be positive definite; sampling from singular normal variance mixtures can be achieved by providing factor.

(d,k)-matrix such that factor %*% t(factor) equals scale; the non-square case $k \neq d$ can be used to sample from singular normal variance mixtures. Note that this notation coincides with McNeil et al. (2015, Chapter 6). If not provided, factor is internally determined via chol() (and multiplied from the

qmix

df

scale

loc

factor

right to an (n, k)-matrix of independent standard normals to obtain a sample from a multivariate normal with zero mean vector and covariance matrix scale).

method character string indicating the method to be used to obtain the sample. Avail-

able are:

"PRNG": pseudo-random numbers,

"sobol": Sobol' sequence,

"ghalton": generalized Halton sequence.

If method = "PRNG", either qmix or rmix can be provided. If both are provided, rmix is used and qmix ignored. For the other two methods, sampling is done via

inversion, hence qmix has to be provided and rmix is ignored.

skip integer specifying the number of points to be skipped when method = "sobol",

see also example below.

weights d-numeric vector of weights.

s numeric vector of length 1 or n giving the value of the constrained sum; see

below under details.

... additional arguments (for example, parameters) passed to the underlying mixing

distribution when rmix or qmix is a character string or function.

Details

Internally used is factor, so scale is not required to be provided if factor is given.

The default factorization used to obtain factor is the Cholesky decomposition via chol(). To this end, scale needs to have full rank.

Sampling from a singular normal variance mixture distribution can be achieved by providing factor.

The number of rows of factor equals the dimension d of the sample. Typically (but not necessarily), factor is square.

rStudent() and rNorm() are wrappers of rnvmix(, qmix = "inverse.gamma", df = df) and rnvmix(, qmix = "constant", df = df), respectively.

The function rNorm_sumconstr() can be used to sample from the multivariate standard normal distribution under a weighted sum constraint; the implementation is based on Algorithm 1 in Vrins (2018). Let $Z=(Z_1,\ldots,Z_d)\ N_d(0,I_d)$. The function rNorm_sumconstr() then samples from $Z|w^TZ=s$ where w and s correspond to the arguments weights and s. If supplied s is a vector of length s, the i'th row of the returned matrix uses the constraint s0 where s1 is the i'th element in s1.

Value

rnvmix() returns an (n, d)-matrix containing n samples of the specified (via mix) d-dimensional multivariate normal variance mixture with location vector loc and scale matrix scale (a covariance matrix).

rStudent() returns samples from the d-dimensional multivariate Student t distribution with location vector loc and scale matrix scale.

rNorm() returns samples from the d-dimensional multivariate normal distribution with mean vector loc and covariance matrix scale.

 $rNorm_sumconstr()$ returns samples from the d-dimensional multivariate normal distribution conditional on the weighted sum being constrained to s.

skewstudent

Functionalities for the skew-t distribution and copula

Description

Sampling and density evaluation for the multivariate skew-t distribution and copula.

Usage

Arguments

u	(n,d)-matrix of evaluation points or data; Have to be in $(0,1)$.	
x	(n,d)-matrix of evaluation points or data	
n	sample size n (positive integer).	
df	positive degress of freedom; can also be Inf in which case the copula is interpreted as the Gaussian copula.	
loc	location of length d .	
gamma	Skewness-vector of dimension d ; if all(gamma == 0), the classical t distribution or copula results.	
scale	scale matrix (a covariance matrix entering the distribution as a parameter) of dimension (d,d) (defaults to $d=2$). Note that scale must be positive definite,	
factor	(d,d)-matrix such that factor %*% t(factor) equals scale. If not provided, factor is internally determined via chol()	
scale.inv	inverse of scale; if not provided, computed via pd.solve(scale).	
ldet	<pre>log(det(scale)); if not provided, computed via pd.solve(scale).</pre>	
log	logical indicating whether the logarithmic density is to be computed.	
pseudo	logical; if TRUE, copula samples are computed via pobs() from a multivariate skew-t sample. If FALSE, the univariate skew t distribution functions are internally approximated via integrate(); see details below.	
method	see rnvmix().	
skip	see rnvmix().	

Details

Functionalities for sampling from the multivariate skew-t distribution and copula; the former has stochastic representation $\mu + W\gamma + \sqrt{W}AZ$ where $AA^T = scale$, W follows an inverse-gamma distribution with parameters df/2 and is independent of the d-dimensional vector Z following a standard multivariate normal distribution. When gamma is the null-vector, the distribution becomes the multivariate t distribution.

A major computational challenge when working with the skew t copula is the lack of an available distribution and quantile function of the univariate skew t distribution. These are required in

rskewtcopula(, pobs = FALSE) and in dskewtcopula(). The unviarate skew t distribution and quantile functions are currently implemented as described Yoshiba, T. (2018).

The functions described here are currently being further developed to improve stability, accuracy and speed, so that arguments may change in subsequent versions of nvmix.

Value

n-vector of (log-)density values and (n, d)-matrix of samples, respectively.
